PID Tuning Guide (written by silverxxx)

This text is taken from here

Ok , the pids look something like this in file pid.c (rate) and anglepid.c (for level)

```
Quote:
// Kp ROLL PITCH YAW
float pidkp[PIDNUMBER] = { 17.0e-2 , 17.0e-2 , 10e-1 };
// Ki ROLL PITCH YAW
float pidki[PIDNUMBER] = { 15e-1 , 15e-1 , 50e-1 };
// Kd ROLL PITCH YAW
float pidkd[PIDNUMBER] = { 6.8e-1 , 6.8e-1 , 5.0e-1 };
// output limit
const float outlimit[PIDNUMBER] = { 0.8 , 0.8 , 0.4 };
// limit of integral term (abs)
const float integrallimit[PIDNUMBER] = { 0.8 , 0.8 , 0.4 };
in the brackets, the first number is roll, second pitch, and last is yaw.
```

Generally the roll and pitch are the same for square frames.

So you have kp, ki and kd which are the 3 terms of the pid.

Then there is outlimit, that sets the max pid output. In this case the output is at 0.8, or 80% thrust max for pitch and roll, and 40% for yaw (because more yaw makes it unstable)

The integrallimit is similar, but applies to the Ki Iterm only. It can be set the same as outlimit, or smaller.

About the numbers used: because this are float numbers, and there are radians somewhere in the program, the p, i, and d terms are very small, so they use the scientific notation, in order to not have to type many zeros.

```
So 17e-2 = 17 * 10 to the power(-2) = 0.17 and 15e-1 = 1.5
```

There are also large positive numbers in some places, for instance 1e6 is 1000000

Level mode tuning:

In level mode, the firmware uses both rate and angle pid, and as such, it's best to have the quad tuned in acro mode before fine-tuning level mode. The level mode pid settings are found in file "anglepid.c"

Level mode is pretty easy to tune as it usually only needs P or PI (it will fly ok with P only). For quick tuning set P only, and set I to zero.

Acro mode tuning:

It's possible to have the quad fly with P and D only, and that is probably the fastest way to tune it

since only 2 numbers are required. From PD to PID generally the P term can be reduced about 30%-50% and I term increased to a value where there are no side effects.

I'd start with D of 5e-1 and find a P that works well. If the quad flies, it's easy to increase D, as a d that's too high can generally either be heard, or induce very fast oscillations. If the guad is drifty (and hard to control) it needs more P, if it oscillates after a change of angle, it needs less.

A P that is too high will cause oscillations after a stick input. In this case, either decrease P or increase D

The I term can have all sorts of effects, and it is also affected by P (and vice-versa) so it's best to either leave it last, or have a small one (or zero) The I term can cause some overshoot, or it can cause drift if its zero and P and D are not high enough. It can also cause oscillations that get worse with time. In case of overshoot, lower I term or increase P term.

Note that a quad with P and D only will only fly well if the motors produce similar thrusts, and the quad is built straight.

The D term usually creates the "locked in" feel. The higher the D term, the more "locked in" the quad will feel, and also will cope better with wind and other issues. A higher D will also allow a higher P to be used, hence increasing control response. Too high D will cause very fast oscillations, and it may also cause "jumpyness", the quad seemingly jumping up/down. The jumpiness is caused by vibrations (mainly from the motors), as the D term is vibration sensitive.

A unusual method to check how good the quad is tuned is to hit it while hovering with an object (ruler / pencil) slighty, on one of the corners. If it oscillates afterwards, either/both P or I are too big or D is too small.
